## ABSTRACT

Shipboard repair part allowances are presently computed using the Fleet Logistics Support Improvement Program which only considers individual part failure rate data and shipboard population. Two alternate allowance determination models are evaluated which consider other logistics factors when computing allowances. One model maximizes repair part availability using marginal analysis techniques and the other model optimizes system availability. The effectiveness of the three different models are compared for four different systems using the NAVSEA TIGER simulation program. The comparisons show that large improvements in system measures of effectiveness can be achieved using the alternative model which optimizes system availability without any increase in total investment costs for allowances. The alternative marginal analysis model did not produce consistently better results over all system configurations than did the FLSIP model.

## U. INTRODUCTION

The United States Navy presently determines repair part allowance quantities for most shipboard applications using procedures established under the Fleet Logistics Support Improvement Program (referred to as the FLSIP model). The FLSIP model was designed before the development of highly sophisticated and powerful third and fourth generation computer hardware and software systems. As a result, in its allowance computations, the FLSIP model considers only individual parts usage data and the total population of each part aboard the ship for which allowances are being computed. FLSIP was also designed to support systems which were much less complex and technologically advanced than those being supported in the Navy of the 1980s and 1990s.

To adjust to changes in technology, improved methods for determining shipboard allowance quantities for repair parts must be developed. To the extent that these improved methods can be supported (by computer technology, data collection procedures, etc.) they should include consideration of as many of the other factors in the logistics environment as possible. This would include system configuration, maintenance policy, operational scenario, supply response times, replacement times, component repair times, spares sharing, and the time horizon mission profile. Due to the escalating costs of repair parts, the increased emphasis on cost efficient management in the military and the likelihood of increasingly restrictive cost constraints on inventory levels in the military, these new allocation methods should attempt to optimize with respect to system availability for any fixed cost in inventory investment.

This paper evaluates two shipboard allowance determination models as alternatives to the FLSIP model. A relatively simple marginal analysis model is evaluated which considers the marginal increase in repair part availability to be gained per dollar spent when determining what repair parts should be allowed. This model requires unit cost data in addition to the data required for the FLSIP model. A much more complex optimization model which focuses on maximizing system availability is also evaluated. In addition to the data required for the FLSIP model, the availability model considers equipment unit cost, equipment Mean Time To Repair (MTTR), total budget constraint, and system configuration data. These models are discussed in detail in Chapter III.

An amended version of the NAVSEA TIGER simulation model is used to compare the effectiveness of each of the three allowance determination models under many different scenarios. Chapter II discusses the capabilities and uses of the amended TIGER simulator. A complete printout of the amended TIGER programs and specific instructions for their use are provided in Appendices B and C. An example of running each allowance determination model on the TIGER simulator is provided in Chapter IV. The results of all the comparisons made during this research are provided in Chapter V.

## II. NAVSEA TIGER SIMULATION MODEL

### A. INTRODUCTION

The TIGER simulation model is a set of programs developed within NAVSEA to evaluate the performance of complex shipboard operating systems using various measures of effectiveness. This model was modified so that it was compatible with the Naval Postgraduate School computer system in September 1980 by Leather [Ref. 1]. However, due to a complete replacement of hardware and partial replacement of software in December 1980, the model had to be further modified to be compatible with the new computer system. All allowance computations and simulations were run on the IBM system 3033 using the programs in Appendix C. Once data inputs were prepared, an allowance computation and simulation of 1000 missions could be run interactively on a computer terminal in two to six seconds of computer time. All modifications are included in the programs provided in Appendix C.

The TIGER simulation model considers the effect of the following system parameters:

- the Mean Time Between Failures (MTBF) of the equipments/components in the system
- the MTTR of the equipments/components in the system
- the interactions between various equipments/components in the system (as reflected in a reliability block diagram of the system)
- the number of spare parts available to support the system
- the operating cycle for the system and the various components of the system

Before running a system, the appropriate data for the above parameters for that system must be input into the TIGER simulator as discussed in Appendix B. Most of the inputs have to be specified exactly, however the TIGER simulator will compute repair part allowances if that is desired. As originally written, the number of repair parts authorized in a system could be specified exactly or a subroutine could be utilized which would compute repair part allowances for the system under FLSIP procedures (which are utilized by the Navy Ships Parts Control Center to actually determine repair part allowances for Navy ships). FLSIP procedures are discussed in detail in Chapter 3, section A. For this research, two additional subroutines were written for the TIGER simulation model so that repair part allowances for a system could also be computed using the Marginal Analysis model discussed in Chapter 3, section B or using the Availability model discussed in Chapter 3, section C. The main program was also modified to accept spare part unit costs and total budget constraints as input parameters for these models.

## B. TIGER OPERATION

The TIGER simulator utilizes Monte Carlo random number techniques to estimate part failure times and times to repair based on the assumption that the times between failures for each part are exponentially distributed with parameter MTBF and the repair time for each part is exponentially distributed with parameter MTTR. The operating status of all parts is then observed at all times during the simulation to determine when the system is "up" and when it is "down". The TIGER simulator considers the inter-relationships between the parts (as specified in the reliability block diagram) to determine whether the system is "up" or

"down". When an acceptable combination of parts are operational then the system is considered to be "up". During those periods of time when an acceptable combination of parts are not operational, the system is considered to be "down".

The TIGER simulator measures the effectiveness of a system using the observed "up" and "down" times for that system over a specified number of missions. The length of each mission is included as an input parameter. The number of missions simulated is also specified in the input parameters and must be between 50 and 1000 (in increments of 50). System effectiveness is computed in the following four ways:

1) Estimated reliability is the probability that a system will perform satisfactorily during an entire mission.

$$REL(EST) = 1 - \frac{\text{Number of Mission Failures}}{\text{Total Number of Simulated Missions}}$$

2) Estimated Instant Availability is the probability that the system will be in an "up" condition at a specific point in time.

$$AVA INSTANT(EST) = \frac{\text{Number of Missions Up at Time (t)}}{\text{Total Number of Missions Simulated}}$$

This value is calculated at the beginning and end of each phase sequence. A mission can contain up to six different operating scenarios. These are defined as phase sequences. For example, for simulating shipboard operations: one phase can represent in port periods, another can represent normal steaming operations, and a third can represent battle engagement periods. The ability to replace parts and the amount of time a part must be operational for the equipment to be considered in an "up" status can be varied from one

phase type to another. Details for doing this are discussed in Appendix B under Card Types 7, 10 and 13.

3) Estimated Average Availability is the probability that the system will be in an "up" condition at a random point in time.

$$\text{AVA AVERAGE (EST)} = \frac{\text{Summation of Uptime for All Missions Simulated}}{\text{Summation of Total Mission Calendar Time for all Missions Simulated}}$$

4) Estimated readiness is the probability that the system will be in an "up" condition at a random point in time assuming that the system stays down for the remainder of each mission after its first failure in that mission.

$$\text{RED (EST)} = \frac{\text{Summation of Uptime for all Missions Simulated (through the first failure)}}{\text{Summation of Total Mission Calendar Time for all Missions Simulated}}$$

Estimated instant availability and estimated average availability were used to evaluate the three allowance determination models in this research.

#### C. PECULIARITIES OF USE IN THIS THESIS

Since the objective of this research was to measure the relative effectiveness of three different repair part allowance determination policies, many of the parameters in the TIGER simulator which could have been varied were not. The following input parameters were held constant throughout this research.

1. Timeline phases. Scenarios can be specified where reliability block diagrams change during different phases of the mission timeframe being simulated. For the purposes of this study, only one phase was used for all simulations which lasted the entire length of each mission.

2. Mean Time To Repair. MTTR was established as one hour for all equipments.

3. Allowable Downtime. Equipments can be allowed to fail for a certain length of time without causing the system to fail regardless of their position in the reliability block diagram by having specified allowable downtimes. The allowable downtimes for all equipments used in this research were set to zero.

4. Three Levels of Repair Parts Support. Additional support from repair parts located at an intermediate level supply activity (ie. a destroyer tender) and at a depot level supply activity (ie. a Naval Supply Center) can be simulated. However, since the objective of this research was to evaluate the effectiveness of shipboard allowances, it was assumed that no support could be obtained from intermediate or depot level activities during the 90 day mission involved.

#### D. TIGER OUTPUT

The TIGER simulator produces both standard and optional outputs. The various options are discussed in Appendix B under the Printout Option Card. The optional output used for this research was the management summary printout. It first displays most of the user's input, the allowance determination model used to compute repair part allowances (if one was used), and the number of repair parts being used.

The TIGER simulator then prints a message every time the system goes down indicating which components are down and when they will come back up. Since this portion of the output was voluminous and not useful for analysis during this research, it was suppressed.

Next the TIGER simulator prints the cumulative measures of effectiveness for the system after each group of 50 missions has been simulated. Since this portion of the output was voluminous and not useful until all simulations were completed, it was suppressed until the last mission simulation was completed.

The TIGER simulator then produces tables which summarize data about specific equipment failures, the number of repair parts used, and critical equipments.

Examples of the various outputs produced by the TIGER programs are provided in Appendix D. A detailed explanation of these outputs is provided in Reference 4.

### III. ALLOWANCE DETERMINATION POLICIES

#### A. FLEET LOGISTICS SUPPORT IMPROVEMENT PROGRAM (FLSIP) CONCEPT

The FLSIP concept is presently used by the Ship's Parts Control Center (SPCC) to determine repair part allowances for most shipboard applications. It requires two inputs. First, the average usage rate (on an annual basis) must be known for each repair part. This is denoted as the Best Replacement Factor (BRF). Since most initial usage data available to the Navy is in the form of MTBF data, it must be converted for use in the FLSIP model. Since MTBF is measured in hour units and BRF is measured in annual units, the hourly MTBF data must be divided into 8760 (the number of hours in a 365 day year) to get a BRF figure. The formula for conversion is:

$$\text{BRF} = \frac{8760}{\text{MTBF}}$$

Second, the total number of times each repair part is installed in the various equipments aboard the ship must be known. This is known as the shipboard population (POP). These two numbers are then multiplied to get the expected number of failures for each part aboard that ship in a one year period of time. This is taken as the mean for each part.

$$\text{mean annual demand} = \text{BRF} \times \text{POP}$$

Ignoring minimum replacement units, technical overrides, etc., the shipboard allowances for each repair part are then determined as follows.

1. If the mean annual demand for a part is greater than or equal to 1.0, the shipboard allowances will be based on anticipated demand. The allowance will be set equal to the minimum number of spares that will provide at least a 90% probability that actual demand for the part during a 90 day period will not exceed the allowance quantity (assuming a Poisson distribution of demand).

2. If the mean annual demand for a repair part is greater than or equal to .25 but less than 1.0, the shipboard allowance will be set to one. These allowances are insurance items. (.25 is the insurance item cut point - also known as the FLSIP cut point.) Several years ago, as a result of funding pressures, this cut point was adjusted up from .15 to reduce the number of insurance items allowed. It can be adjusted up or down to provide more or less insurance protection for certain types of ships but the main emphasis in this paper will be with the .25 level.

3. If the mean annual demand for a part is less than .25 (or other specified cut point), no shipboard allowance will be established.

Funding constraints for shipboard repair parts can be accommodated by increasing the FLSIP cut point as discussed above. However, since almost all the parts used in the systems being evaluated for this paper were assumed to be

high failure rate parts, a change of the FLSIP cut point has little effect on the value of parts required to support those systems. This is due to the fact that most of the means were greater than 1.0 so the allowances were based on demand and adequate repair parts were allowed to meet the 90% issue criteria regardless of the insurance item (FLSIP) cut point. Even if the cut point were changed from .25 (ie. one demand every 4 years) to 1.0 (ie. one demand every year), the FLSIP computed allowances would exceed the budget constraints desired in most cases considered in this thesis.

Note: A study conducted by the Center For Naval Analysis [Ref. 2] has recommended the following changes to the FLSIP model:

- a. Items supporting equipments essential to a primary mission of the ship would be identified and the insurance item stockage threshold for these items would be lowered to .10 (one unit demanded in 10 years), and
- b. High demand insurance items would be stocked in insurance quantities of two each instead of one each as is now done.

This revised FLSIP model was not considered in this research.

Since changing the FLSIP cut point was not considered to be an effective way to constrain expenditures for the FLSIP model for the systems analyzed for this paper, the availability objective of the model was varied instead. By varying the availability objective, a budget constraint could effectively be introduced into the FLSIP model. To do

this, the probability of not being out of stock in the FLSIP model was allowed to decrease until a low enough probability was reached to allow a set of FLSIP allowances to be computed within a specified budget constraint. The specified availability started at 90% and was decreased in increments of 5%. At each increment, FLSIP allowances were determined using the decreased probability and the cost of the repair parts was computed. If the total cost of repair parts was less than the funding constraint specified, then that FLSIP repair parts list was used. If the cost exceeded the funding constraint, that repair parts list was discarded and another set of FLSIP allowances were determined using a 5% lower specified availability. This procedure is illustrated on Table I.

Note that some of the different availability levels have the same allowance costs. This is true because they have the same allowance levels. Different availability levels can have the same allowance levels because repair part allowances do not change linearly with availability levels. Since repair parts must change in increments of one, the change in expected availability may decrease substantially by deleting one part. For example, if a part has an MTBF of 1720 hours, the probability of having no demands in a 90 day period is 28%. So protection levels between zero and 28% can be obtained without carrying any spares. If, on the other hand, one spare is carried, a protection level of 64% is obtained. So protection levels between 29% and 64% all require that one spare be carried. For the program written for this research, that means that protection levels of 60%, 55%, 50%, 45%, 40%, 35% and 30% would all require an allowance of one. Not until the required availability level reached 25% would there be a change in the allowance for this part.

TABLE I

## Use of the Availability Objective in the .25 FLSIP Model

The availability objective is varied in the .25 FLSIP model to facilitate the computation of allowances within specified budget constraints. The use of the availability objective for this purpose is demonstrated with the following system.

Part Number	MTBF	POP	MEAN ANNUAL DEMAND	Unit Cost
-----	-----	---	-----	-----
1	25000	1	.34	150.00
2	1500	1	5.84	151.00
3	750	1	11.68	152.00
4	750	1	11.68	153.00
5	1500	1	5.84	154.00
6	7500	1	1.17	155.00
7	7500	1	1.17	156.00
8	2500	1	3.40	157.00

For this system, unconstrained .25 FLSIP allowances would cost \$3058.00 as shown on the 90% availability line below. To determine the allowances when the funding is constrained to 75% of the fully funded costs (ie. 2293.50), the amended TIGER FLSIP procedure is:

- 1st: Set the high limit for the constrained allowances to 5% higher than the specified limit (the high limit here is  $\$2293.50 \times 1.05 = \$2408.18$ ). This is done to ensure that optimal combinations just slightly above the specified budget constraint will be considered.
- 2nd: Compute spares required for various availability objectives (starting at 90% and going down 5% at a time) until a set of spares is found which will be less than the budget limit high as shown below.

% AVAIL OBJECT	COST	Number of Repair Parts							
		Part #1	Part #2	Part #3	Part #4	Part #5	Part #6	Part #7	Part #8
-----	-----	-----	-----	-----	-----	-----	-----	-----	-----
90	\$3058	1	3	5	5	3	1	1	1
85	3058	1	3	5	5	3	1	1	1
80	2448	1	2	4	4	2	1	1	1
75	2448	1	2	4	4	2	1	1	1
70	2448	1	2	4	4	2	1	1	1
65	2143	1	2	3	3	2	1	1	1

Since \$2143 is less than \$2408, the repair parts computed at the 65% availability objective will be used as the allowances for the 75% funding level.

## B. MARGINAL ANALYSIS CONCEPT

One of the deficiencies of the FLSIP model as now used is that it ignores the cost of the spare parts in its computations and in the decision process. The FLSIP model is also very limited in its ability to adjust to funding constraints because this is presently only done by adjusting the insurance cut point. This can result in the inefficient allocation of budget dollars due to variances in the relationships between the unit costs and the reliabilities of the various repair parts. The marginal analysis concept, on the other hand, does consider the cost of the individual items and is designed to accommodate a budget constraint on the total amount of dollars available for spare parts. There are many different possible marginal analysis policies. The one evaluated in this paper selects that combination of parts (for a given set of parts) that will provide the highest total parts availability for a given dollar value constraint. Four inputs are required for this concept. The following three inputs must be known for each part: MTBF, total number of parts in the system, and the unit cost. In addition, a total dollar value constraint for the repair parts allowance must be known. The shipboard repair part allowances are then determined by stepwise adding an additional spare for that item showing the greatest increase in probability of a fill per dollar spent. The incremental improvement in the probability of a fill is the difference

$$P_i(X_i \leq x) - P_i(X_i \leq x-1) ,$$

where  $x$  is the number of spares of item  $i$  and  $X_i$  is the demand for spares of item  $i$ . This turns out to be

identically equal to the probability of a demand for exactly  $x$  spares or  $p_i(x) = P(X_i=x)$ . The policy is illustrated with a simple example involving only the three parts shown in Figure 3.1.

<u>Part Number</u>	<u>MTBF</u>	<u>Pop</u>	<u>Mean 90 Day Demand</u>	<u>Unit Cost</u>
1	1720	1	1.26	\$ 200.00
2	1720	1	1.26	50.00
3	3000	1	.72	100.00

Figure 3.1 Example System for Marginal Analysis Model

Step 1. First, we want to determine the marginal benefit (in probability of filling demands) of adding a single spare of each item. For our example:

$$p_1(1) = .35634142 \quad p_2(1) = .35634142 \quad p_3(1) = .3518585$$

Step 2. Then for each part, we determine the marginal benefit to cost ratios by dividing the values in step 1 by the unit cost of the part. For our example:

$$\frac{p_1(1)}{c_1} = .0017817 \quad \frac{p_2(1)}{c_2} = .0071268 \quad \frac{p_3(1)}{c_3} = .0035186$$

The resulting value is the marginal benefit per dollar invested of adding one of each of the parts.

Step 3. The part with the highest ratio calculated in step number 2 is assigned a single spare. For our example,

the part with the highest marginal availability is part number 2.

Step 4. The total cost of all assigned repair parts is then compared to the budget constraint. For our example, the current total cost of assigned repair parts is \$50.00 as shown in Figure 3.2. If the constraint has been reached or exceeded, the computations are concluded with the parts allowances assigned to that point. If the budget constraint has not been reached, the model continues on to step 5.

<u>Part Number</u>	<u>Allowance</u>	<u>Unit Cost</u>	<u>Total Cost</u>
1	-0-	\$200.00	-0-
2	1	50.00	50.00
3	-0-	100.00	-0-
Total Costs			<u>\$50.00</u>

Figure 3.2 Total Costs of Allowances Assigned After First Iteration

Step 5. A revised marginal availability is calculated for the part which was assigned an allowance in step 3. One additional spare is now considered for that part and the probability of that many demands in a 90 day period is calculated. For our example, the revised marginal availability for part number 2 is  $p_2(2) = .22701228$ . The new marginal benefit to cost rate for this item is then computed by dividing the revised marginal availability of the item by its unit cost. For our example:

$$\frac{p_2(2)}{c_2} = \frac{.22701228}{50} = .00454024$$

The model then brings along the information from step 2 for those items not selected for an increase in spares in step 3 and repeats the same type of comparison as was done in step 3. For our example, the benefit to cost rates are now:

$$\frac{p_1(1)}{C_1} = .0017817 \quad \frac{p_2(2)}{C_3} = .00454024 \quad \frac{p_3(1)}{C_3} = .0035186$$

The next spare will again be assigned to part number 2 since it still shows the maximum rate.

The above process continues until the specified budget constraint is reached.

### C. AVAILABILITY CONCEPT

The availability of equipments and systems afloat are a function of many factors as discussed in Chapter 1. One weakness of both the FLSIP and Marginal Analysis models is that neither of them considers many of those factors. They, in essence, ignore many operational issues which should be considered by a model of this type to be as accurate as possible. Another weakness of both of those models is that the measure of effectiveness for the system is not system related and consequently, one cannot relate resources to readiness (ie. system availability). Man Won Jee [Ref. 3: ch. 4], developed a mathematical model for computing repair part allowances to support any given system. The model optimizes the instant operational availability of a system for any given budgetary constraint. This is referred to as the Availability model. The Availability model improves upon both the FLSIP and Marginal Analysis models by including several more of the pertinent operational factors. Those factors included in the Availability model which are not considered in either of the other models are the Mean

Time To Repair (replace) a component and a consideration of the interactions between the various components in the system. Like the Marginal Analysis model, the Availability model also considers the unit cost of each repair part and the total budget constraint on the repair parts allowed. In addition, the Availability model improves upon the FLSIP and Marginal Analysis models by relating resource utilization to optimizing system availability which is the measure of effectiveness.

For a single component system, Jee showed that the availability after  $t$  units of time of a component having  $n$  spares is given by

$$A^{(n)}(t) = A^{(n-1)}(t) + ((f * g)^{(n)} * \bar{F})(t)$$

where  $f(t)$  is the probability density of component lifetimes,  $g(t)$  is the probability density of replacement times,  $\bar{F}(t) = P(T \geq t)$  and  $(f * g)^k$  represents the  $k$ -fold convolution of  $f$  and  $g$ .

Jee further showed that for the special case in which

$$f(t) = ((\lambda)(e))^{-\lambda(t)} \quad ; \text{and}$$

$$g(t) = ((\nu)(e))^{-\nu(t)} \quad ;$$

the marginal contribution that the  $n$ th spare provides to system availability is:

$$(f^{(k)} * g^{(k)} * F)(t) =$$

$$\begin{aligned} & \left(-\frac{t}{s}\right)^k * \left(-\frac{t}{k!}\right)^k + \sum_{r=1}^k (-1)^r * \frac{(k+r-1)^p}{r! s^r} * \frac{t^{(k-r)}}{(k-r)!} e^{-lt} \\ & + (-1)^{k+1} * \left(-\frac{t}{s}\right)^{k+1} * \frac{t^{(k-1)}}{(k-1)!} + \sum_{l=1}^{k-1} \frac{(k+1)^p}{l! s} * \frac{t^{(k-1-l)}}{(k-1-l)!} e^{-nt} \end{aligned}$$

where:  $l = \text{lambda}$ ,  $n = \text{nu}$ ,  $0 = \text{ln}$ ,  $s = n-1 = 0$ , and

$$n^p_k = \frac{n!}{(n-k)!}.$$

The above formula is referred to as the JEE formula throughout this paper. All systems analyzed in this paper were assumed to have parts with exponentially distributed times between failures and replacement times so the JEE formula is used for all calculations. An example of the results of using the JEE formula to determine the contribution to system marginal availability of individual spares is shown in Table II. A maximum of 9 spares for a given part are allowed when using the JEE formula in the amended TIGER model written for this research effort.

Jee then developed a repair parts allocation algorithm that utilizes the JEE formula to optimize the instant operational availability of a system by efficiently allocating the number of spares for each component in a "k" component system [Ref. 3: ch. 6]. The algorithm he developed is basically a dynamic program which is then used to determine the most efficient combination of repair parts for each budget amount.

TABLE II

## JEE Formula Computations: An Example

Data for Sample System:

Part Number	MTBF	MTTR
-----	-----	-----
1	1000.0	10.00
2	5000.0	10.00
3	3000.0	10.00

Parts 2 and 3 are in parallel. Part 1 is in series with the combination of parts 2 and 3.

The availabilities for each part number for a range from zero to nine repair parts computed by the JEE formula are:

AVAILABILITY MATRIX FOR SPARE 1 IS:

Part No	Allow Qty	Cost	Avail
----	----	-----	-----
1	0	0.0	0.115325
1	1	150.00	0.365767

3	7	1064.00	0.996677
3	8	1216.0	0.996667
3	9	1368.00	0.996667

The sample system shown in Table II will be used to illustrate how the JEE algorithm works. Part numbers 2 and 3 will be used as the first two dynamic programming stages in our illustration. The stage returns from the first two stages are simply the results of initially calculating the marginal contributions of repair parts 2 and 3 using the JEE formula as shown in Table II. These stage returns are then assembled into the matrix shown on Table III so that a sequence of maximum returns from the combination of these two stages can be calculated.

The JEE algorithm always starts in the upper left hand corner of the matrix because that is the minimum cost combination for the two stages being considered. This is the first undominated combination on the matrix. The algorithm determines the cost and system availability of using the combination of repair parts specified at that junction in the matrix. The cost is calculated by simply costing out the repair parts specified at that point. The calculation of the resulting system availability depends upon whether the parts are operating in series or in parallel. If the parts are in series, the system availability is:

$$AVAIL_{sys} = AVAIL_1 * AVAIL_2 .$$

If the parts are in parallel, the system availability is:

$$AVAIL_{sys} = 1 - (1 - AVAIL_1) * (1 - AVAIL_2) .$$

Parts 2 and 3 shown on Table II are in parallel and the results of the above calculations for the first undominated combination in the matrix on Table III are a cost of \$0.0 and an availability of .8199. The same calculations are then made for other pertinent blocks in the matrix. For example, the cost of combining three spares for part number

TABLE III

## JEE Algorithm Matrix \*

Part Numbers		0	1	2	3	4	5	6
		-0-	151	302	453	604	755	906
3	2	.6492	.9289	.9886	.9970	.9979	.9980	.9980
0	.4868	<u>.8199</u>	<u>.9635</u>	<u>.9941</u>	<u>.9985</u>	<u>.9989</u>	.755	.9990
1	.8368	.9427	.9884	.9981	<u>.9995</u>	.9996	.9997	.907
2	.9614	.9865	.9973	<u>.9996</u>	<u>.9999</u>	.9999	.9999	.1059
3	.9908	.9968	.9993	.9999	.9999	.9999	.9999	.1211
4	.9959	.9986	.9997	.9999				.910
5	.9966	.9988	.9998	.9999				.1062
6	.9967	.9988	.9998					.1063
7	.9967	.9988	.9998					.1215

\* The top and side rows in the matrix show the number of spares, the total of their unit costs and availability contribution of each of the parts indicated. The numbers within the matrix show the total costs and resulting availabilities from combining the numbers of spares indicated.

2 with three spares for part number three is \$909 and the resulting availability for this same combination is .9999. The calculations do not have to be made for all combinations as discussed in detail by Jee [Ref. 3: ch. 6].

Next, the JEE algorithm finds that combination in the matrix which has a combined cost less than any other combination with a system availability larger than that of the previous undominated combination. That combination is the next optimal combination in the matrix. This process is repeated until all undominated combinations on the matrix have been identified (a maximum of 99 undominated combinations can be processed using the amended TIGER model written for this research effort). The first 8 undominated combinations are indicated on Table III. The optimal repair parts allocation at any dollar level can be identified by simply following the arrows on the matrix until the specified dollar level is found. For example, on Table III, a combination of three spares for part #2 and zero spares for part #3 would be optimal for budget levels between \$453 and \$603 while a combination of four spares for part #2 and zero spares for part #3 would be optimal for a budget level of \$604.

The undominated combinations from the matrix in Table III are the returns from stage 3. These returns are then combined with the cost and availability data for the part (or combination of parts) in the next stage of the system. In Table IV, the undominated combinations from Table III are combined with the costs and availabilities for part 3 from Table II. As discussed on Table II, these parts are assumed to be in series. The resulting first eight undominated combinations are shown on Table IV. As can be observed from Table IV, a combination of 4 spares for part #1, 1 spare for part #2, and 0 spares for part #3 is optimal for budget levels between \$751 and \$900, etc.

TABLE IV

## JEE Algorithm Matrix \*

Part Numbers	0 0	1 0	2 0	3 0	4 0	3 1
2,3	0 0	1 1	2 2	3 3	4 4	3 5
1	.8199	.9635	.9941	.9985	.9989	.9995
0 .1153	<u>.0945</u>	.1111	.1146	453	604	755
1 .3658	<u>.2999</u>	.3524	.3636			
2 .6352	<u>.5208</u>	.6120	.6315			
3 .8265	<u>.6776</u>	<u>.7963</u>	.8216			
4 .9276	<u>.7605</u>	<u>.8937</u>	.9221			
5 .9698	.7951	<u>.9344</u>	.9641			
6 .9844	.8071	.9485	.9786			
7 .9887	.8106	.9526	.9829			

\* The top and side rows in the matrix show the number of spares, the total of their unit costs and the availability contribution of each of the parts indicated. The numbers within the matrix show the total costs and resulting availabilities from combining the numbers of spares indicated.

This combining of matrices is continued until all the parts in the system are included in one of the two axes of the final matrix. Then the optimal combination of repair parts can be identified for any dollar level by looking at the undominated allocations for that matrix.

#### IV. EXAMPLE OF EACH ALLOWANCE DETERMINATION MODEL

##### A. INTRODUCTION

The TIGER programs in Appendix C automatically compute repair part allowances and run simulations using those allowances under the operating scenarios specified in the input data. The output produced are in three sections:

- 1) the input deck printout;
- 2) the allowance computation output; and
- 3) the simulation output.

The input deck printout and simulation output have the same format for all three allowance determination models and are explained in detail in Reference 4, section 4. The allowance computation output was added for this research effort and is different for each of the allowance determination models. The allowance computation outputs are discussed in detail in this chapter. Comparisons between the effectiveness of the three allowance determination models are made in Chapter 5.

The system shown in Figure 4.1 will be used to demonstrate the processing of each allowance determination model. Each of the eight parts are assumed to be unique and have the unit prices and MTBFs shown. The allowances being developed are to sustain operations for 90 days. The format in which the data is input into the programs in Appendix C is discussed in detail in Appendix B.

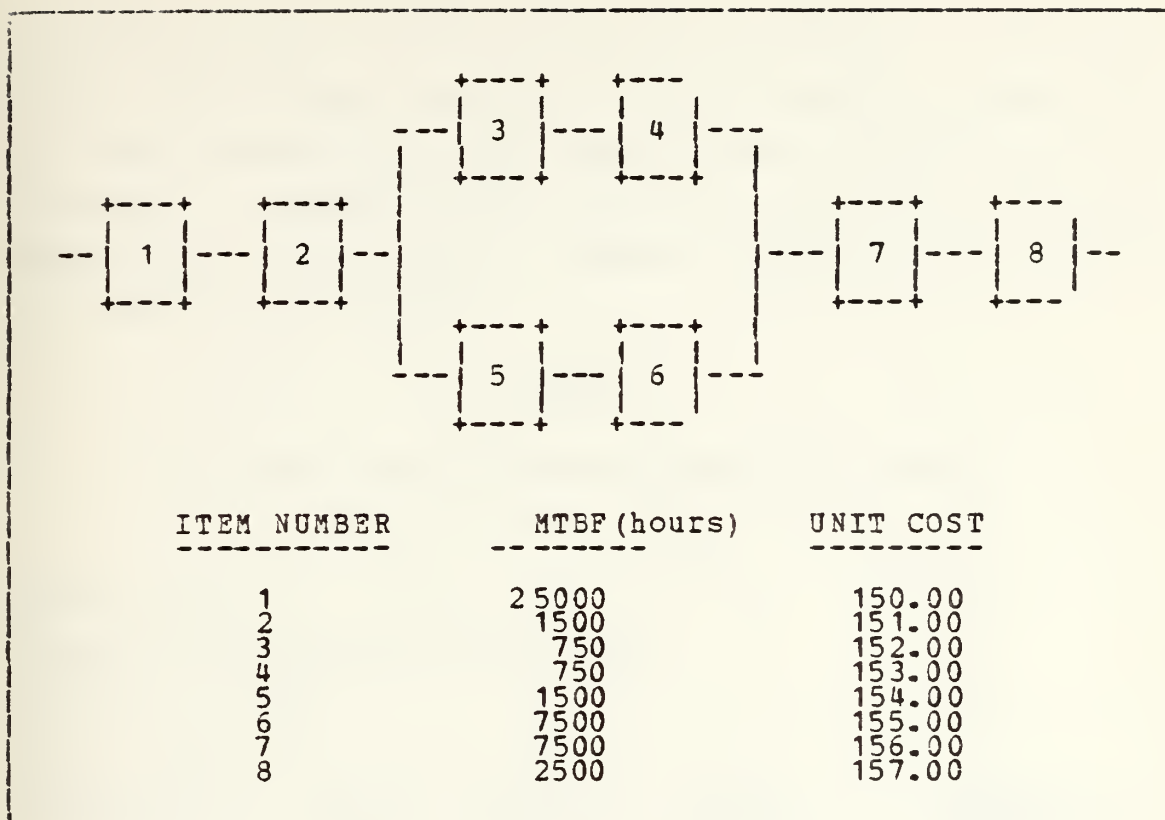

Figure 4.1 Example System

#### B. EXAMPLE OF AN UNCONSTRAINED .25 FLSIP MODEL

Table V is the allowance computation output for an unconstrained .25 FLSIP model allowance for the system in Figure 4.1. For an unconstrained FLSIP allowance, the budget specified must be large enough to ensure that all insurance items will have an allowance equal to one and that all demand based items will have an allowance adequate to satisfy 90% of all expected demands during a 90 day period as discussed in Chapter 3, section A.

The first line of output shown is the budget constraint being used. This is shown after the letters "BUDH" which stand for "Budget-High Limit". In our example, the budget

constraint is \$10,498.95. This is 5% higher than the actual budget constraint of \$10,000 which was input. A 5% flexibility in the budget constraint was selected to ensure that any FLSIP computations that would be just slightly over the constraint specified would still be used for comparison purposes. This was done to ensure the FLSIP model compares as favorably as possible.

TABLE V

FLSIP Example: Allowance Computation Output

BUDH 10498.95

SPARES BEING COMPUTED USING FLSIP

XAVAIL = 0.9000

XSUM = 3058.00

SPARES	TYPE	SHIP	TENDER	BASE	FACTOR
	1	1	0	0	999.00
	2	3	0	0	999.00
	3	5	0	0	999.00
	4	5	0	0	999.00
	5	3	0	0	999.00
	6	1	0	0	999.00
	7	1	0	0	999.00
	8	1	0	0	999.00

The next two lines of output specify that the FLSIP model is being used and what availability probability was used to determine the .25 FLSIP allowances. All computations start at the 90% level (ie-computations produce allowances adequate to provide a 90% probability that the ship will have as many repair parts as demands for repair parts during any given 90 day period of time).

The fourth line of output is the total cost of all allowances required to satisfy the probability level previously specified. This cost is shown after the letters

"XSUM". If XSUM is less than or equal to BUDH, then the repair parts computed during that step will be used as the repair parts for this model. If XSUM is greater than BUDH, then the probability level will be reduced by 5% and another set of repair parts will be computed. In our example, XSUM for the 90% probability level is \$3058.00 which is less than the budget limit of \$10498.95 so the repair parts computed for this level are used.

The number of spare parts are the last thing shown on this part of the output page. In our example, item numbers (spares type) 1,6,7 and 8 are each assigned one shipboard spare, item numbers 2 and 5 are each assigned three shipboard spares and item numbers 3 and 4 are each assigned five shipboard spares.

For this research, it was assumed that no support could be received from sources other than the shipboard allowances so no spares are assigned to the tender or base levels of supply. The 999.00 in the "FACTOR" column indicates that the allowances shown were determined by the program instead of specified so the 999.00 should be ignored. When spares are specified, the number in this column is a spares multiplier which is explained fully in Appendix B under Card Type 18.

#### C. EXAMPLE OF A 100% FUNDED MARGINAL ANALYSIS MODEL

When the Marginal Analysis model uses the total costs of an unconstrained .25 FLSIP model allowance as the budget constraint, it is referred to as a 100% funded Marginal Analysis model. For the system in Figure 4.1, the cost of the allowances computed using the unconstrained .25 FLSIP model were \$3058.00; so \$3058.00 will be used as the budget constraint for the 100% funded marginal analysis model processing for that system.

TABLE VI

## Marginal Analysis Example: Allowance Determination Output

SPARES WILL BE DETERMINED WITH MARGINAL ANALYSIS

BUDGET IS 3058.

THE COST OF ITEM 1 IS 150.00

THE COST OF ITEM 2 IS 151.00

THE COST OF ITEM 3 IS 152.00

THE COST OF ITEM 4 IS 153.00

THE COST OF ITEM 5 IS 154.00

THE COST OF ITEM 6 IS 155.00

THE COST OF ITEM 7 IS 156.00

THE COST OF ITEM 8 IS 157.00

ALL SPARES HAVE BEEN COMPUTED

SPARES	TYPE	SHIP	TENDER	BASE	FACTOR
1		0	0	0	999.00
2		3	0	0	999.00
3		5	0	0	999.00
4		4	0	0	999.00
5		3	0	0	999.00
6		1	0	0	999.00
7		1	0	0	999.00
8		2	0	0	999.00

The allowance computation outputs for a Marginal Analysis allowance determination model are different from those for the FLSIP model as shown on Table VI. The first line of output for the Marginal Analysis model is the statement that spares are determined using Marginal Analysis. The budget constraint and unit cost of each item are then printed as well as a statement indicating that all allowances have been computed. The allowance quantities are printed last. For the marginal analysis model, item numbers 6 and 7 are each assigned one spare, item number 8 is assigned two spares, item numbers 2 and 5 are each assigned three spares, item number 4 is assigned four spares, item 3

is assigned five spares and item number 1 is not assigned any spares. Note the differences in the allowances computed using the FLSIP and Marginal Analysis models. The total cost of the allowances determined by the Marginal Analysis model are only \$2912.00 compared to \$3058.00 for the FLSIP model because the next most cost effective part would have made the total investment in the Marginal Analysis model higher than that of the FLSIP model. Since the system presently in use is the FLSIP system, all unavoidable advantages in comparisons were given to the FLSIP system.

#### D. EXAMPLE OF A 100% FUNDED AVAILABILITY MODEL

When the Availability model also uses the total costs of an unconstrained .25 FLSIP model allowance as the budget constraint, then the Availability model is referred to as a 100% funded Availability model.

The allowance computation outputs for the Availability allowance determination model are different from the other models as shown on Table VII. The first line of output for the Availability model is the statement that spares were computed using the JEE formula. JTIME and TOTSPR are simply printouts of the input data on the JEE Data card. JTIME equals the number of hours simulated (90 days X 24 hours) and TOTSPR is the maximum number of spares which can be considered for any one repair part; for this example the TOTSPR used was 9. The availability matrix for each spare is then computed. After the availability matrix for the last spare has been printed, the output will indicate that the JEE algorithm has been entered.

Table VII shows the optimal allowances for the 100% funded availability model for the system in Figure 4.1. Item numbers 1, 6 and 7 are each assigned two spares, item number 8 is assigned four spares, item numbers 2 and 5 are

each assigned five spares, and item numbers 3 and 4 are not assigned any spares.

If an optimal combination of spares can be determined by the algorithm, the last output will show the quantities of spares computed. However, there are two reasons why the computation of an optimal combination of spares may not be possible. First, the program can handle a maximum of only 9 spares for any given repair part. So, if the optimal solution has any repair parts with more than 9 spares, it cannot be computed. Second, the maximum number of undominated combinations which can be handled by the program is 99 and, if more than 99 undominated combinations are required in any matrix to reach the desired budget constraint, then the optimal solution cannot be computed. If this condition exists, the output will print: "OPTIMAL SOLUTION CANNOT BE COMPUTED". Even though an optimal solution cannot be computed, a set of spare parts will be generated and printed. It should be remembered however that these allowances are not optimal.

#### E. BUDGET CONSTRAINED EXAMPLES

Any dollar amount can be used as a budget constraint for the three allowance determination models. The FLSIP model will not compute allowances any higher than required to meet its insurance and availability objectives and therefore may not use all funds available. The marginal analysis and availability models will keep assigning spares until the budget constraint is reached.

For this research effort, the performance of the models was observed at budget constraints which were less than necessary to provide fully funded .25 FLSIP allowances. Examples are provided below for the allowance computation outputs for the three models using a budget constraint equal

to 75% of the costs of an unconstrained .25 FLSIP allowance for the system in Figure 4.1. The 75% budget constraint is equal to \$2295.00.

The allowance computation outputs for the 75% funded .25 FLSIP model are shown on Table VIII. The program had to compute allowances at six different availability levels before it found one that would produce allowances costing less than the budget constraint (see Chapter 3, section A, for an explanation of this process). At the 90% and 85% availability levels, the allowances computed would cost \$3058.00, and at the 80%, 75%, and 70% availability levels, the allowances computed would cost \$2448.00. Different availability levels can have the same costs as discussed in detail in Chapter 3, section A. All of these allowance alternatives are more costly than the allowed budget. Not until the computation of the 65% availability level is an allowance combination reached (costing \$2143.00) which is less than the budget constraint. The combination of repair parts computed as the 65% allowance level is then used in the TIGER simulation program to compute availabilities.

The allowance computation outputs for the 75% funded Marginal Analysis model are shown on Table IX. The only differences in the output for the 75% funded model and the 100% funded model (Table VI) are the budget constraint used and the allowances specified. The printout for the marginal analysis model does not show the different steps the program is going through to determine the allowances as does the .25 FLSIP model. However, the constrained runs do produce different allowances as can be seen by comparing Tables VI and IX. The 75% funded allowances have one additional spare for item number 1 but have one less spare for item numbers 2, 3, 4, 5 and 8.

## V. EVALUATION AND COMPARISON OF THE MODELS

### A. SYSTEMS USED FOR EVALUATION

The four systems shown on Figures 5.1 through 5.4 were used to evaluate the three allowance determination models. The systems were selected to illustrate the relative effectiveness of the models in situations where the degree of designed-in system redundancy differs significantly. For example, System A has no designed-in redundancy and will fail whenever any one of the eight components fails whereas System D has a significant degree of designed-in redundancy and will not fail as long as components 1, 8 and 6 or 7 don't fail or components 1, 8 and 2 or 3 and 4 or 5 don't fail.

Figure 5.1 System A

Figure 5.2 System B

Figure 5.3 System C

Figure 5.4 System D

## B. SCENARIOS USED FOR EVALUATION

The twenty-seven different scenarios shown in Table XI were used in evaluating the three allowance determination models for each of the four systems discussed above.

Since the Marginal Analysis and Availability models explicitly consider component costs and MTBF as part of the allocation algorithm, the three models were compared on systems having a range of variabilities in component unit costs and MTBFs. Any advantages offered by algorithms which consider unit costs should be most apparent for cases in which unit cost variabilities are high. Likewise, any

\* based on the budget for the Unconstrained .25 FLSIP allowance list

advantages offered by algorithms which consider the MTBFs of the parts in the system should be most apparent for cases in which MTBF variances are high. So as not to bias the results in favor of any given model, comparisons were also made for cases in which the variability in unit costs and MTBFs were low. The three different sets of part costs shown in Figure 5.5 and the three sets of part MTBF data shown in Figure 5.6 were evaluated.

<u>Part Number</u>	<u>Case A</u>	<u>Case B</u>	<u>Case C</u>
1	\$150.00	\$150.00	\$ 50.00

Standard Deviation	2.45	59.76	217.12

Figure 5.5 Part Cost Sets

Since the Marginal Analysis and Availability models are designed to accomodate funding restrictions and the FLSIP model is not, any advantages offered by the former models should be most apparent for cases in which funding constraints are severe. So as not to bias the results in favor of the alternative models, comparisons were also made for systems where funds were adequate to fully fund FLSIP allowances. Thus, the allowances provided by each model for each combination or scenario of part costs and MTBFs were

Part Number	Case 1	Case 2	Case 3

Standard Deviation	- 0 -	6,095	8,222

Figure 5.6 Part MTBF Sets

determined for 100% (unconstrained), 75%, and 50% funding levels. The unconstrained funding level was based on a fully funded .25 FLSIP allowance for each scenario.

The parts required for a .25 FLSIP allowance to support each system under each scenario were determined first. The cumulative cost of those parts was then established as the 100% funding level. This 100% funding figure was then used as a constraint to establish allowances for each scenario using the Marginal Analysis and Availability models. Next, the funding available was constrained to 75% and 50% of the unconstrained FLSIP funding level for each system and scenario. Spares allowances were determined by using each of the three models for a given constrained funding.

### C. TEST RESULTS

The results of running the TIGER simulations for the four systems and the 27 scenarios discussed above are shown in Tables XII and XIII. Each system was simulated over 1000

missions (the maximum allowable in the TIGER simulator). A random number seed of 2222 was used for all simulations. The results include both average availability and instant availability.

Of the three allowance determination models, the availability model is the only one which considers system design. The advantages of considering system design when computing repair part allowances are clear in the example used in Chapter 4 (see Figure 4.1). That system is referred to in this chapter as the "B" system. The cost data and MTBF correspond to cases A and 3, respectively. The allowances computed by each allowance determination model for the "B" system are shown in Figure 5.7.

Since the FLSIP system ignores configuration, it assigns the highest number of spares (5 each) to part numbers 3 and 4 since they are expected to fail the most often and are therefore assumed to need the most support. Since the costs of the parts in this system are almost identical, the marginal analysis model essentially assigns spares (in this situation) to those parts which are expected to fail the most since that maximizes the number of demands that will be filled. This procedure results in almost the same allowances as the FLSIP model.

The Availability model recognizes that there is a more reliable parallel leg which can be supported more cost-effectively and therefore assigns no spares to part numbers 3 and 4. This action leaves extra money available to provide additional support to the other non-redundant parts in the system and results in a 10% improvement in system availability over the FLSIP model allowances and an 8% improvement in system availability over the Marginal Analysis model allowances. The availabilities, both average and instantaneous, listed in Tables XII and XIII are 89/91/98.

	FLSIP	MA	AVA
	----	--	---
Total % Greater Than 90% Availability	50	46	65

- a - budget constraint was too low to compute a FLSIP allowance  
b - optimal combination could not be reached

The overall results of the Marginal Analysis model were somewhat disappointing. For the data collected in Tables XII and XIII, the Marginal Analysis model outperformed the FLSIP model only 37% of the time for average availability (FLSIP did better 43% of the time and they tied 20% of the time) and 31% of the time for instant availability (FLSIP did better 16% of the time and they tied 53% of the time). It also achieved greater than 90% average availability only 46% of the time compared to 50% of the time for FLSIP and 65% of the time for the Availability model. Because of the relatively poor performance of this model compared to the FLSIP model, no further analyses will consider the Marginal Analysis model.

As would be expected, the improvements produced by the Availability model over the FLSIP model are always greater in instant availability than in average availability because the Availability model was designed to optimize instant availability. However, the Availability model also always resulted in the same or higher average availability than did the FLSIP model. Of course, in a given simulation, one might observe that the FLSIP model produces higher availability than does the Availability model just due to chance fluctuation. Indeed this happened for scenarios Case B/Case 1 for 50% funding, Case C/Case 1 for 50% funding, and Case A/Case 2 for 100% funding under System A on Table XII. Subsequent simulation runs using different random number seeds yielded the expected results with the Availability model outperforming the FLSIP model with respect to system availability.

As shown on Table XIV, the level of part cost variance has little influence on availability under the FLSIP model while the level of MTBF variance does significantly affect availability. This is as expected since the FLSIP model

does explicitly consider MTBF (through the demand rate) but it does not consider part costs.

As shown on Table XIV, the part cost variability has some effect on system availability when the availability model is used. However, the variability in MTBF's has a much more significant effect. Since the systems evaluated in Table XIV are fully funded systems, it appears that in the Availability model the influence of MTBF variance and system configuration are much more important in determining parts allowances than part costs are when the system is relatively well funded.

For both the FLSIP model and the Availability model, the level of availability improves as the systems become more redundant. The general improvement in availability as system redundancy increases is expected from reliability theory. As shown on Table XV, the percentage improvement with the Availability model is much higher than with the FLSIP model. This could also be anticipated since the Availability model is an optimization model which would increasingly enhance the reliability of a system as the system became more and more reliable itself; while the FLSIP model would provide the same level and type of support to

a - FLSIP allowances could not be computed at budget constraint specified

NOPT - an optimal solution could not be obtained using the Availability Model

The FLSIP system is designed to have a 90% probability of not running out of a specific part during a 90 day mission. This part availability goal cannot be converted directly to an equipment availability goal; however it is of interest to compare how often systems were available at least 90% of the time under each model. As shown at the bottom of Table XII for average availability, allowances developed using the .25 FLSIP model achieved 90% availability only 50% of the time while allowances developed using the Availability model achieved 90% availability 65% of the time. For instant availability, the .25 FLSIP model achieved 90% availability only 20% of the time while allowances developed using the Availability model achieved 90% availability 52% of the time as shown on Table XIII. The Availability model shows its greatest advantage over FLSIP for cases in which less than 100% funding was available as shown in Figure 5.8.

#### D. INACCURATE INPUT DATA

One measure of interest when evaluating mathematical models is the "robustness" of the models. That is, how well do the models work when there are deviations from the

assumptions upon which the models are derived. This section examines one such robustness issue. The effectiveness results of the three models are compared for the hypothetical case in which the values input for the MTBF parameters are assumed to be in error. Simulations were run with the 100% funded allowances where the usage rate was assumed to actually be twice as high (MTBF is half as high) as the figures used above to compute the allowances. The results of those simulations are shown on Table XVI.

As before, the effectiveness results are better with the Availability model than with the FLSIP model. However, the improvement afforded by the Availability model is even greater when the MTBF values are lower as shown on Table XVII. In the results summarized in Table XVI, only 17% of the scenarios using FLSIP model allowances achieved an equipment availability of 90% or better while more than 44% of the scenarios using Availability model allowances achieved the 90% criteria. The better performance of the Availability model in this situation is to be expected since it will focus support on those items which are most critical to the operation of the system at the expense of those components which are redundant. Then, since repair parts are concentrated in the critical components, failures more frequent than expected will not have as serious effect on system availability in contrast to the FLSIP model which attempts to cover all the bases.

Repair parts allowances determined using the Availability model often resulted in a smaller range of repair parts being carried than under the FLSIP model. This was particularly true when a severe budget constraint was imposed. For example, the unconstrained .25 FLSIP allowances and the Availability allowances for System D with Case B Part Costs and Case 2 MTBFs are shown in Figure 5.9. Both

of the above allowances cost exactly \$1700.00. The FLSIP allowance resulted in average availability of .9925 while the Availability model allowances resulted in average availability of .9985; so that slightly better availability was achieved with only half the number of line items stocked by the Availability model. This phenomenon is not peculiar to this one case. The Availability model calculated fewer line items than the FLSIP model for every scenario in which the

system being evaluated had any designed-in redundancy. It also calculated fewer line items than the FLSIP model for about one-third of those systems which had no built in redundancy. These results show that separate range and depth calculations are not necessarily needed in repair parts allowance determination models. The single criteria used by the Availability model implicitly excludes many items from range consideration by assigning them an allowance quantity of zero. The Marginal Analysis model reviewed in this research does the same thing.

## VI. SUMMARY, CONCLUSIONS, AND RECOMMENDATIONS

### A. SUMMARY

The NAVSEA TIGER simulation model was modified in this thesis for use in evaluating three allowance determination models: the FLSIP model, the Marginal Analysis model, and the Availability model. The FLSIP model was originally included as part of the TIGER model so that FLSIP repair part allowances could automatically be computed if desired. Subprograms were written for this thesis so that repair parts for the other two models could automatically be computed by the TIGER model also. The modifications to the TIGER model made by Leather [Ref. 1: p.1] were utilized as well as his recommendation for converting BRP data into MTBF data for use in the TIGER model. The allowance computations and simulations were run on the IBM System 3033 located at the Naval Postgraduate School.

Four sample systems with varying degrees of designed-in redundancy were used to evaluate the effectiveness of the allowance determination models. Different combinations of unit cost and MTBF data were also used to evaluate the relative importance of these data elements in each of the models. And finally, different levels of funding availabilities were used to evaluate the robustness of each model with respect to funding constraints.

The effectiveness of each model for every system and scenario was obtained at three funding levels. First, the effectiveness of each model for each system/scenario combination was determined using a budget constraint equal to the cost of the allowances determined using an unconstrained .25 FLSIP model. Then the effectiveness of each model for each

system/scenario combination was determined using 75% and then 50% of the original amount.

The effectiveness of the allowance determination models was measured by the simulated availability of the systems being supported. The measures of effectiveness used were:

$$\text{Average availability} = \frac{\text{Summation of Uptime for All Missions Simulated}}{\text{Summation of Total Mission Calendar Time for all Missions Simulated}}$$

$$\text{Instant availability} = \frac{\text{Number of Missions Up at Time (t)}}{\text{Total Number of Missions Simulated}}$$

## B. CONCLUSIONS

The Marginal Analysis model was not found to be significantly more effective than the FLSIP model and was decidedly less effective than the Availability model from an overall perspective. The Availability model was always at least as effective as the FLSIP model and it significantly outperformed the FLSIP model where funding constraints precluded 100% funded FLSIP allowances and where the MTBF were reduced by 50% to simulate a case of inaccurate failure rate data.

It was observed that changing the FLSIP cut point is not an effective method for accommodating budget constraints in systems with mostly high failure rate components. The FLSIP cut point is the dividing line between those low demand items which should be protected by an "insurance" allowance and those which should not. However, if all or most of the parts in a system have high enough demands to qualify for stocking on a demand based criteria, then changing the FLSIP cut point will not effect the number of these parts carried and therefore cannot be used to accommodate budget constraints. Use of the Availability model is a much more

effective method for accommodating budget constraints in these situations.

There was no significant difference in the effectiveness of systems supported by FLSIP determined allowances and Availability determined allowances when the system was non-redundant. As system redundancy increased, the availability improved for both FLSIP and Availability allowances. However, the magnitude of the improvement was significantly greater with the Availability allowances.

Fully funded .25 FLSIP allowances resulted in 90% system availability only 50% of the time even though the repair parts carried should theoretically have been sufficient to satisfy 90% of all repair part requests. Availability allowances at the same level of funding achieved 90% availability 65% of the time.

Repair part allowances determined using the Availability model often resulted in a smaller range of repair parts carried than did the FLSIP model. This was particularly true when a severe budget constraint was imposed. Finally, the Availability model incorporates both a range and depth capability illustrating that separate range and depth criteria are not required in all allowance determination models.

## C. RECOMMENDATIONS

1. Further analysis of the Marginal Analysis model used in this research is not justified. Other marginal analysis models may be better and could be investigated in the same manner because of the ease in obtaining and entering the minimal amount of data required for this type of model.

2. System availability should be used as the measure of effectiveness for shipboard allowance determination models. This would require that a "standard" of effectiveness be

defined. If the present FLSIP system meets the established availability goals then no further development of allowance determination systems would be required. On the other hand, if the present FLSIP system does not meet the established goals, then further development of an improved allowance determination system would be justified.

3. The use of the Availability model for determining shipboard repair part allowances should be further investigated. The importance of the various variables in the Availability model should be clarified. For example, is an improvement in repair time more important than an improved set of repair part allowances or are actual repair times really needed at all? The types of systems where availability can be improved the most should also be determined; ie. systems with mostly high failure rate parts or low failure rate parts, systems with many components or only a few components, systems with a lot of designed in redundancy or only a little redundancy, etc. The TIGER simulator could be used to evaluate these various factors on a detailed basis.

4. The TIGER simulator or an improved version of a follow-on simulator should be used to evaluate the relative importance of the major factors in the shipboard operating environment which influence system availability (ie. inaccurate MTBF reporting, configuration data, etc.). The TIGER simulator is easy to understand and easy to use. Once input data has been prepared, an allowance computation and simulation of 1000 missions can be run interactively on an IBM 3033 in two to six seconds of computer time. For example, it could be used to evaluate the effect of having bad BRF data when computing shipboard allowances using the FLSIP procedures to see how much emphasis should be placed on

obtaining better data. If equipment availability is relatively insensitive to inaccurate BRF data, then the improvement of data collection techniques can be ignored. If equipment availability is seriously degraded when BRF data is lower than actual failure rates, then the development of improved data collection techniques should be given a high priority. The TIGER simulator could also be used to evaluate what other factors in the logistics system are most pertinent in achieving better equipment availability so that emphasis can be placed on developing allowance determination models that include those important factors instead of factors that are less influential.

SPCC	Navy Ships Parts Control Center

## APPENDIX B

### AMENDED TIGER PROGRAM INPUT REQUIREMENTS

The punched cards or card images discussed in this appendix must be input to utilize the NAVSEA TIGER program as amended for this research effort. A complete printout of the amended program is provided in Appendix C.

Card Type 1. Availability Model Processing Cards.

The Availability Model Processing Cards control the order in which the various parts in a system will be combined to compute optimal repair part allowances for the system when the Availability Model is being used. The first step in preparing this card is to complete a system reliability block diagram similar to Figure B.1.

Figure B.1 Block Diagram Example

Once an accurate reliability block diagram has been prepared, the system availabilities resulting from combining all the individual parts must be computed. This is done by starting with two parts and progressively combining additional parts until all of the parts have been combined. To properly prepare the Availability Model Processing Cards, the system must be analyzed to determine how the individual

components can be combined so that there are never more than two sets of parts combinations. For example, the parts in the system in Figure B.1 could be combined in the following manner:

Combination #1 = (Part 2) and (Part 3)

Next Combination #1 = Previous Combination #1 and  
(Part 1)  
= (Parts 2,3) and (Part 1)

Next Combination #1 = Previous Combination #1 and  
(Part 4)  
= (Parts 1,2,3) and (Part 4)

Combination #2 = (Part 5) and (Part 6)

Next Combination #1 = Previous Combination #1 and  
Previous Combination #2  
= (Parts 1,2,3,4) and (Parts 5,6)

Next Combination #2 = (Part 7) and (Part 8)

Next Combination #1 = Previous Combination #1 and  
Previous Combination #2  
= (Parts 1,2,3,4,5,6) and  
(Parts 7,8)

They could not be combined in the following manner even though the parts combinations are appropriate because the use of three combinations is not allowed:

Combination #1 = (Part 2) and (Part 3)

Next Combination #1 = Previous Combination #1 and  
(Part 1)  
= (Parts 2,3) and (Part 1)

Next Combination #1 = Previous Combination #1 and  
(Part 4)  
= (Parts 1,2,3) and (Part 4)

Combination #2 = (Part 5) and (Part 6)

Combination #3 = (Part 7) and (Part 8)

Next Combination #2 = Previous Combination #2 and  
Previous Combination #3  
= (Parts 5,6) and (Parts 7,8)

Next Combination #1 = Previous Combination #1 and  
Previous Combination #2  
= (Parts 1,2,3,4) and  
(Parts 5,6,7,8)

Once an appropriate flow of combinations has been determined for a system, the worksheet shown on Figure B.2 should be prepared. The first spares to be combined will be shown next to combination 101. In addition, whether they are to be in series or parallel must be coded and all the parts included in the resulting combination should be specified. The next line will show the part number or combination number for the parts being combined in that step, whether they are in series or parallel, and which

parts end up being included in that combination. This process is continued until all parts are included in the last combination. An example of a worksheet filled in for the proper combination of parts in Figure B.1 discussed above is shown in Figure B.3.

An individual Availability Processing Card must then be prepared for each line on the worksheet (in the format provided below). The cards must be input in the same order they appear on the worksheet. One additional card must be added at the end of this deck which has zeros in columns 4, 8 and 12 to signify that all combinations are complete. If the Availability model is not being used, these cards can be left in the input data or only the last card with the three zeros can be input.

### Card Type 3. Cost Cards.

A separate Cost Card must be entered for each part in the format specified below. An example of these cards for the system in Figure B.1 is given in Figure B.6.

Columns	Format	Variable Name	Description
1-8	F8.2	Cost	Cost of each repair part. Costs must be input in the same order as equipment type numbers on Equipment Type cards. Total cards must equal NTOTA on Allowance Model processing card. If cost data is not to be entered, use one card with a cost of \$1.00.

#### Card Columns:

#### Card Type 4. JEE Data Card.

The total mission time and the maximum number of spares allowed for each repair part must be input in the format described below. An example of a JEE Data card for the system in Figure B.1 is shown in Figure B.7 using a 90 day mission time ( $90 \times 24 = 2160$ ) and a maximum number of spares equal to nine.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-8	I8	JTIME	Total Mission Time.
9-12	I4	TOTSPR	Total number of spares for which availability is to be computed using the availability model. Max is 9. If Availability model is not to be used, insert 1 in card column 12.

Card Columns:

      2160      9
```

Figure B.7 JEE Data Card Example

### Card Type 5. Timeline Iteration Card

The number of timeline iterations to be used and the run identification data for the specific run being made are shown on this card. A timeline iteration of one was used for all the simulations done for this research. Additional information for using more than one timeline iteration may be found in reference 4, section 2. The format is described below. An example of a Timeline Iteration Card for the system in Figure B.1 is shown in Figure B.8.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	JCC	Number of timeline iterations to be run for the data deck.
5-80	19A4	RUNID	Alphanumeric run identification information.

Card Columns:

1 .25 FLSIP RUN FOR SYSTEM B1 ON 5/20/82
```

Figure B.8 Timeline Iteration Card Example

## Card Type 6. Statistical Parameter Card.

Statistical parameters for the run are entered on this card. If a predefined fixed number of missions is to be run, set PL = 1.0 and NOPT and NMAX to the desired number of missions. All simulations for this research were run with a fixed number of 1000 missions. If what is desired is to determine whether a system meets a certain level of reliability, that level can be specified in the PL and XK blocks and the simulator will run an adequate number of missions to determine whether the system will meet or fail to meet the specified reliability (PL) within the standard deviation specified (XK) [Ref. 4: p. 2-7]. An example of a Statistical Parameter Card for use with the system in Figure B.1 is shown in Figure B.9.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	NMAX	Maximum number of missions to be run (should be in multiples of 50 and must not exceed 1000).
5-8	I4	NOPT	Optimal number of missions (not to exceed NMAX).
9-12	F4.0	PL	Specification requirement for reliability.
13-16	F4.0	XK	Standard deviation to be used in calculating lower control limit. A value of 1.28 corresponds to a 90% lower confidence limit.
17-20	I4	ISEED	Random number seed.
21-24	I4	NPH	Number of phase types - not to exceed 6.

Card Columns:

10001000 1.01.282222 1
```

Figure B.9 Statistical Parameter Card Example

### Card Type 7. Phase Type and Duration Cards.

This card is used to specify the number of phase types and how long each is to last. The phases can be used to identify different scenarios. For example, for simulating shipboard operations: one phase can represent in-port periods, another can represent normal steaming operations, and a third can represent battle engagement periods. The repair option for each part can be different in each phase as specified on Card Type 10 and the Duty Cycle Utilization of each part can also be different during each phase as specified on Card Type 12. From 1 to 95 phase sequences of not more than six phase types can be specified on these cards. The format for this card is described below. For this research effort, a single phase lasting 90 days (2160 hours) was used for all simulations. An example of this type card is shown in Figure B.10.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-2	F2.0	XXT(1)	Phase type number for first simulation sequence.
3-10	F8.0	XXT(2)	Duration of first sequence.
11-12	F2.0	XXT(3)	Phase type number for second simulation sequence (if any).
13-20	F8.0	XXT(4)	Duration of second phase.
21-22	F2.0	XXT(5)	Phase type number for third simulation sequence (if any).
23-30	F8.0	XXT(6)	Duration of third sequence.
31-32	F2.0	XXT(7)	Phase type number for fourth simulation sequence (if any).
33-40	F8.0	XXT(8)	Duration of fourth sequence.
41 42	F2.0	XXT(9)	Phase type number for fifth simulation sequence (if any).
43-50	F8.0	XXT(10)	Duration of fifth sequence.

Note: If more than 5 phase sequences are needed, continue on additional cards using the same fields. No more than 95 phase sequences are permitted.

Card Columns:

1111111111222222222233333333334444444444555  
1234567890123456789012345678901234567890123456789012  
1.2160.

Figure B.10 Phase Type and Duration Card Example

Card Type 8. \*\*\*\*\* Blank Card \*\*\*\*\*

Card Type 9. Printout Option Card

This card is used to select which printout option is to be used. The format is as follows.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	KOPT	Printout option switch = 1 for management summary = 2 for engineering summary = 3 for complete details (used for debugging only) = 4 to suppress printout of input data = 5 to specify printout using KS variables below = 6 for TIGER/MANNING complete details (debugging only)

If KOPT 5 is used, select from the following output options as needed (otherwise leave the fields blank):

5-8	I4	KS (1)	= 1: Input data
9-12	I4	KS (2)	= 1: equipment down at time of mission failure
13-16	I4	KS (3)	= 1: down time at end of phase
17-20	I4	KS (4)	= 1: abort messages
21-24	I4	KS (5)	= 1: all events
25-28	I4	KS (6)	= 1: ETIME matrix
29-32	I4	KS (7)	= 1: not used
33-36	I4	KS (8)	= 1: not used
37-40	I4	KS (9)	= 1: not used
41-44	I4	KS (10)	= 1: system & subsystem status
45-48	I4	KS (11)	= 1: TIGER/MANNING debugging
49-52	I4	KS (12)	= 1: status of all groups
53-56	I4	KS (13)	= 1: downtime message

### Card Type 10. Phase Repair Card

This card is used to specify the repair option for each phase up to a total of six. The format is as follows:

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	IFLAG(1)	Repair option for each phase type (up to 6):  = 0 if on-board repair allowed in the phase  = 1 if no on-board repair allowed in the phase  = 2 if on-board repair allowed but failure inhibited
5-8	I4	IFLAG(2)	
9-12	I4	IFLAG(3)	
13-16	I4	IFLAG(4)	
17-20	I4	IFLAG(5)	
21-24	I4	IFLAG(6)	

### Card Type 11. Repair Policy Card.

This card is used to establish repair policy for the simulation being run. REPOL determines what percentage of repairs will be made at the shipboard level as opposed to the intermediate and depot level. Since this research evaluates shipboard support only, REPOL was set equal to 1.0 for all simulations.

A part can be allowed to fail for a certain period of time before its failure causes the system to be in a down status by specifying an allowable downtime in the TAD2 field. For this research, all mission allowable downtimes were set equal to zero.

Specified MTBFs and MTTRs can be changed for a given simulation run by using a value other than 1.0 in the XM and XT fields.

The format for the card is:

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	F4.0	REPOL	Decimal fraction of repairs to be performed aboard ship
5-12	F8.2	TAD2	Mission Allowable Downtime
13-16	F4.0	XM	MTBF Multiplier. Default = 1.0
17-20	F4.0	XT	MTTR Multiplier. Default = 1.0

## Card Type 12. Equipment Type Cards

Equipment type cards are used to input the specific parameters for each type of equipment (repair part) being evaluated. A separate card must be input for each type of equipment. The TIGER simulator can accommodate various equipment operating rules and variable duty cycles for each piece of equipment (these options were not utilized for this research). A detailed discussion of these items can be found in Reference 4, chapter 2. The format for these cards is provided below. An example of these cards for the system in Figure B.1 is shown in Figure B.11.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	I	Equipment type numbers-should be assigned sequentially starting at 1, not to exceed 200.
5-20	4A4	F1	Equipment type description
21-28	F8.0	XMTBF	Mean Time Between Failure
29-32	F4.0	XMTTR	Mean Time to Repair/replace Non-repairable is indicated by 9999.
33-36	F4.0	U	Duty cycle utilization (non-zero decimal fraction).
37-40	F4.0	V	Administrative delay time from tender to ship
41-44	F4.0	W	Administrative delay time from depot to ship.
45-48	I4	IUI	Used for variable duty cycles. See Reference 4, chapter 2 for an explanation.

[illegible]

Figure B.11 Examples of Equipment Type Cards

Card Type 13. Variable Duty Cycle (VDC) Card.

This is an optional card. It is used if variable duty cycles are used. See chapter 2 of Reference 4 for details of its use.

Card Type 14. Variable Mean Time to Repair Card.

This is an optional card. It is used if variable Mean Times to Repair are used. See chapter 2 of Reference 4 for details of its use.

Card Type 15. \*\*\*\* Blank Card \*\*\*\*

### Card Type 16. Equipment Cards.

Each individual piece of equipment (repair part) in the system being evaluated must be given a unique number to identify it. These cards identify which equipment type each specific equipment (repair part) is. There must be one card for each equipment type and they must be input sequentially by equipment type number in the format specified below. For this research, the aspects of spares sharing were not considered because the calculations developed by JEE [Ref. 3], are different for scenarios where spares are shared. To use the Availability model developed for this research, each equipment number must be assigned its own equipment type even if the parameters for two or more equipments are identical.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	NTYPE	The type number associated with the equipment listed in the next field or fields.
5-8	I4	LOAD(1)	Equipment numbers of those equipment which belong to the designated equipment type - up to 19 equipment per card (if there are more than 19 equipment associated with a given type, use additional equipment cards and repeat the same type number). The largest equipment number allowed by the program is 500. The total number of equipments must not exceed 500. No gaps are allowed between equipment 1 and the largest assigned equipment number.
9-12	I4	LOAD(2)	
13-16	I4	LOAD(3)	
17-20	I4	LOAD(4)	
21-24	I4	LOAD(5)	
25-28	I4	LOAD(6)	
29-32	I4	LOAD(7)	
33-36	I4	LOAD(8)	
37-40	I4	LOAD(9)	
41-44	I4	LOAD(10)	
45-48	I4	LOAD(11)	
49-52	I4	LOAD(12)	
53-56	I4	LOAD(13)	
57-60	I4	LOAD(14)	
61-64	I4	LOAD(15)	

65-68	I4	LOAD(16)
69-72	I4	LOAD(17)
73-76	I4	LOAD(18)
77-80	I4	LOAD(19)

Card Type 17. \*\*\*\* Blank Card \*\*\*\*

Card Type 18. Spares Model Card.

This card is used to specify whether spares will be input directly or whether spares will be computed using one of the allowance determination models. The options for this card are:

a) Use the literal "Unlimited Spares" in columns 1 through 16 to simulate unlimited spares. The program then assigns 90,000 spares for each equipment or repair part. This option was not used during this research.

b) Use a blank card if spares are going to be specified. Then input the desired number of spares for each equipment or repair part on the spares cards which follow. (This option was used to simulate the use of inaccurate MTBF data by computing allowances with one set of MTBF data and then specifying those allowances using this option and inputting different MTBF parameters for comparison.) If spares have been specified and the effect of using a different level of support are needed, this effect can be obtained by inserting a spares multiplier (SX) in card columns 21 to 24 of this card. The program will then use the number of spares assigned times the spares multiplier specified.

c) Use "999." in columns 21 to 24 to use the allowance determination model specified on the Allowance Model card (Card Type 2).

### Card Type 19. Spares Cards.

These cards are only used if the allowances for spares are going to be specified exactly (columns 1 through 16 of the Spares Model card must be empty and columns 21 through 24 must have something other than .999). One of these cards must be input for each equipment type being used. These cards must be input in order starting with Equipment Type 1 in the following format:

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	I4	ISPARE(1)	Number of organizational level spares (on board) for the equipment type.
5-8	I4	ISPARE(2)	Number of spares at the tender for the equipment type.
9-12	I4	ISPARE(3)	Number of spares at the base (depot) for the equipment type

NOTE: For each phase type, a set of the remaining cards  
 (except the optional output and demo decks which  
 appear once) must be placed consecutively in the  
 data deck.

A separate reliability block diagram must be prepared  
 for the simulation runs on the TIGER simulator. It is  
 different than the reliability block diagram previously  
 discussed for Availability model processing because it does  
 not have to relate only two groups at a time. For the TIGER  
 simulator, equipments must be aggregated into systems,  
 subsystems, and groups. A system is a set of equipments for  
 which availability is being measured. A subsystem is a set  
 of equipments which, if the set fails, will cause the system  
 to fail. A group is any set of equipments.

For the reliability block diagram for the TIGER  
 simulator, each parallel subset of equipment and each series  
 subset are assigned group numbers. For the example shown in  
 Figure B.1, the groups could be as shown below. Group  
 numbers must be between 501 and 1000 and are arbitrarily  
 assigned below.

Group Number	Equipments in Group	Series/Parallel
-----	-----	-----
501	2 and 3	Parallel
502	5 and 6	Series
503	7 and 8	Series

Once each subset of parallel or series equipments has been assigned a group number, the identified groups are then aggregated into groups of groups which are in parallel or series and these groups are assigned numbers. For the equipments in Figure B.1, the next set of groups could look like those shown below.

Group Number	Equipments in Group	Series/Parallel
-----	-----	-----
601	1, 4, and 501	Series
701	502 and 601	Parallel
888	503 and 701	Series

This process is continued until all the parts in the system can be identified in one group (known as a subsystem group). The subsystem groups are then combined with any remaining equipment which are in series and assigned a final group number (known as the system group). For our example, Group # 701 would be a subsystem group and the system group would be composed of subsystem group # 701 and the series group # 503. For illustrative purposes, the system group will be assigned Group number 888. The method for inputting these relationships into the TIGER simulator are discussed under card types 20 through 23.

Figure B.12 Example of System, Subsystem, and Group Numbering

## Card Type 20. System Card.

This card is used to identify the different systems being evaluated. The format for this card is as follows:

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	A4	ID	Any alphanumeric (ie. the literal "SYST") used to identify the specific system
5-8	I4	LL	Phase type number (sequential) The max value is 6.
9-12	I4	NSS	Number of subsystems in phase (varies only from 1 to 37).
13-16	I4	ISS	System identification number (usually last group number on the configuration matrix cards).
17-24	F8.0	SSTIME	System allowable sustained down time (should not be less than subsystem TAD1 values). Should be less than or equal to TAD2 (repair policy card). To inhibit aborts use a value of 100,000.

An example of the System Card for the system in Figure B.12 is:

```
+-----+
| Card Columns:                                     |
|           111111111122222222222233333333333444444444455 |

| SYST    1    1 888    0.0 |
+-----+
```

## Card Type 21. Subsystem Cards.

This card is used to identify the different subsystems being evaluated. The format for this card is as follows:

Columns	Format	Variable Name	Description
1-4	A4	ID	Any alphanumeric (ie. the literal "SS1").
5-8	I4	LL	Phase type number.
13-16	I4	ISS	Subsystem identification number. This is a group number for a group defined on a configuration matrix card (see below). Each designated subsystem group must be a group that, upon its failure, causes the system to fail.
17-24	F8.0	SSTIME(2)	Subsystem allowable sustained downtime (TAD1). This value should be less than or equal to SSTIME on the system card. To inhibit aborts use a value of 100,000.

An example of the Subsystem Card for the system in Figure B.12 is:

Card Columns:

```
111111111112222222222233333333333444444444455

551 1 701 0.0
```

## Card Type 22. Configuration Matrix Cards.

This card is used to identify the different groups in the systems being evaluated. The format for these cards is as follows:

Columns	Format	Variable Name	Description
1-4	I4	NRO	The number of members in the group defined on this card that are required to be operational and in an up state.
5-8	I4	IB (1)	The group number assigned to the group of members defined on this card. It may vary from 501 to 1000.
9-12	I4	IB (2)	The numbers of the equipment and groups which make up the group defined on this card. The max number of members in a group is unlimited; however, if there are more than 7, a continuation card is required, which is of the same format. The number required and master group number must be identical on all continuation cards.
13-16	I4	IB (3)	
17-20	I4	IB (4)	
21-24	I4	IB (5)	
25-28	I4	IB (6)	
29-32	I4	IB (7)	
33-36	I4	IB (8)	

An example of the Configuration Matrix Cards used for the system in Figure B.12 is:

Card Columns:																																						
1111111111222222222222333333333333444444444455

2	502	5	6																																			
1	503	7	8																																			
3	601	1	4																																			
1	701	502	601																																			

Card Type 23. Equipment Operating Rule Cards.

Operating rules can be specified which will turn selected equipments on and off in predetermined situations. These operating rules were not utilized during this research. All equipments ran all of the time except when they were inoperable. A detailed discussion of the use of this option can be found in Reference 4, chapter 3.

Card Type 24. \*\*\*\* Blank Card \*\*\*\*

Card Type 25. Optional Output Card.

Optional output tables can be selected by using this card as shown below.

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	A4	SPRS	Place any alphanumeric (ie. "SPR") in this field if a table of spares usage is desired.
5-8	A4	APPL	Place any alphanumeric (ie. "APL") in this field if a summary table of equipment that caused mission failures and system downtimes is desired.
9-12	A4	GMMA	Place any alphanumeric (ie. "GMA") in this field if the gamma distribution output is desired.
13-16	A4	DEMO	Place any alphanumeric (ie. "DEMO") in this field if a sequential probability ratio test plan for the system being analyzed is desired. If this option is exercised, an additional card, 26, is required.

### Card Type 26. DEMO Information Card.

This card must be included if DEMO is specified on the Optional Output Card. A detailed discussion of the DEMO Option is provided in Reference 4, chapter 3. The format for this card is as follows:

<u>Columns</u>	<u>Format</u>	<u>Variable Name</u>	<u>Description</u>
1-4	F4.0	A	Producer Risk.
5-8	F4.0	B	Consumer Risk.
9-12	F4.0	R	Discrimination Ratio.

The following are optional inputs.

13-16	F4.0	HAD	X-axis accept intercept (Delta)
17-20	F4.0	HRD	X-axis reject intercept (Delta)
21-24	F4.0	YD	Trucation line accept (Delta)
25-28	F4.0	SLD	Slope (Delta)
29-32	I4	KD	Truncation line reject (Delta)
33-36	I4	ITIME	Number of sets
37-40	I4	ITER	Number of simulations per set
41-44	I4	N	Random number initializer

The total input required for the system in Figure B.12 is shown in Figure B.13.

## APPENDIX D

### TIGER PROGRAM OUTPUT EXAMPLES

The TIGER simulator produces both standard and optional outputs. The various options are discussed in Appendix B under the Printout Option Card. The optional output used for this research was the management summary printout. It first displays most of the user's input, the allowance determination model used to compute repair part allowances (if one was used), and the number of repair parts being used. An example of this output is shown in Table XVIII. A detailed explanation of the entries on Table XVIII is provided in Reference 4.

The TIGER simulator then prints a message every time the system goes down indicating which components are down and when they will come back up. An example of this output is shown in Table XIX. A detailed explanation of the entries on Table XIX is provided in Reference 4. Since this portion of the output was voluminous and not useful for analysis during this research, it was suppressed.

The TIGER simulator then prints the cumulative measures of effectiveness for the system after each group of 50 missions has been simulated. An example of this output is shown in Table XX. A detailed explanation of the entries on Table XX is provided in Reference 4. Since this portion of the output was voluminous and not useful until all simulations were completed, it was suppressed until the last mission simulation was completed.

The TIGER simulator then produces tables which summarize data about specific equipment failures, the number of repair parts used, and critical equipments. An example of this

output is shown in Table XXI. A detailed explanation of the entries on Table XXI is provided in Reference 4.

TABLE XX  
50 Mission Summary Data

RELIABILITY PHASE 1, 1, IS	0.0	INSTANT AVAILABILITY	1.000
READINESS	IS 0.2187	RELIABILITY UP TO PHASE 1	1.000
AVERAGE AVAILABILITY	IS 0.8215	READINESS	IS 0.2187
		AVERAGE AVAILABILITY	IS 0.8215
		INSTANT AVAILABILITY	IS 0.7600

A GRAND TOTAL OF 100 MISSIONS HAVE BEEN RUN.

THE RELIABILITY IS 1.0  
THE LOWER CONF LIMIT IS 0.0  
THE SPEC REQUIREMENT IS 1.0000  
THE READINESS IS 0.2187  
THE AVERAGE AVAILABILITY IS 0.8215  
THE INSTANT AVAILABILITY IS 0.7600

THE MEAN TIME BETWEEN MISSION FAILURES IS 472.0  
THE LCL, SD, MTBMT IS -93.4  
THE MTBF VARIANCE IS 195431.0

THE SYSTEM MTF IS 415.3  
THE SYSTEM FDI IS 84.698  
ANOTHER SET OF 50 MISSIONS WILL BE RUN TO OBTAIN REQUIRED STATISTICAL CONFIDENCE.
